ABSTRACT

The charging of dust grains in astrophysical environments has been investigated with the assumption that these grains are homogeneous spheres. However, there is evidence which suggests that many grains in astrophysical environments are irregularly shaped aggregates. Recent studies have shown that aggregates acquire higher charge-to-mass ratios due to their complex structures, which in turn may alter their subsequent dynamics and evolution. In this paper, the charging of aggregates is examined including secondary electron emission and photoemission in addition to primary plasma currents. The results show that the equilibrium charge on aggregates can differ markedly from spherical grains with the same mass, but that the charge can be estimated for a given environment based on structural characteristics of the grain. The "small particle effect" due to secondary electron emission is also important for de terming the charge of micron-sized aggregates consisting of nano-sized particles.

1. INTRODUCTION

Dust, an ubiquitous component in the universe, plays an important role in the thermodynamics and chemistry of the interstellar and intergalactic medium, interstellar gas dynamics, and the formation of stars, planets, and planetesimals (Jones 1997). Cosmic dust grains also interact with electromagnetic radiation nearby, altering the observed spectra of remote objects (Draine 2003). The study of cosmic dust has steadily gained attention as technological advances makes in situ measurements and sample collection within the heliosphere feasible. Various space missions have been conducted to probe and investigate the composition, size distribution, and structural characteristics of interstellar and interplanetary dust, such as *Ulysses*, *Cassini,* and *Galileo* (Altobelli et al. 2003; Krüger et al. 2010a, 2010b). These dust grains provide an excellent window into interstellar and interplanetary processes, carry information on the origin and evolution of their parent bodies, and reveal the intrinsic properties of the environments where these grains originate. The in situ measurements also provide opportunities to test and validate various theories related to cosmic dust.

Dust grains in the solar system environment are subject to three charging processes (Mendis & Rosenberg 1994)—for dust grains close to the Sun, strong UV radiation can excite and liberate photoelectrons from the surface of the dust grain and charge the grain positively. At the same time, free moving electrons and ions in the solar wind constitute plasma charging currents, although the strength of the currents may be less than the photoelectric charging current (Kimura & Mann 1998a). Between the termination shock and the heliopause, the boundary of the heliosphere, the plasma temperature rises to 2×10^6 K as a result of the constant interaction between the interstellar medium and the solar wind. Secondary electron emission then becomes the dominant charging process (Kimura & Mann 1998a).

Ascertaining the charge on cosmic dust grains in the solar system is essential for several reasons. First, charged grains are subject to the Lorentz force, which can significantly alter their trajectories. When performing on-board measurements and sample collection, the grain dynamics must be taken into account to identify the origin of the measured/captured grains. Second, the high plasma temperature between the termination shock and the heliopause highly charges interstellar dust grains entering the solar system. The smaller mass grains are affected most strongly by the Lorentz force caused by the magnetic field at the heliopause. As a result, their trajectories are significantly altered and these grains have a much smaller probability of reaching the inner solar system. Space missions devoted to studying the interstellar dust in the inner solar system have to take this filtering effect into account (Frisch et al. 1999; Landgraf 2000; Linde & Gombosi 2000). Third, grain charging theory has successfully explained many astrophysical phenomena, such as the mysterious spokes of Saturn's B ring and the lunar "horizon glow" due to dust levitating above the moon's surface (Mitchell et al. 2006; Stubbs et al. 2006).

Charging of cosmic dust grains has been examined in detail due to the reasons listed above (Feuerbacher et al. 1973; Draine & Salpeter 1979; Mukai 1981; Chow et al. 1993; Kimura & Mann 1998a). However, most of the previous work assumes a simple geometry for dust grains, such as a homogeneous sphere. Dust grains naturally occurring in space constantly go through formation processes such as nucleation, condensation, coagulation, and destruction, and as a result they assume more complex structures such as ellipsoids or fluffy aggregates. Aggregates are a common structure for interplanetary, cometary, and interstellar dust. The data and samples collected from space have shown that a porous fluffy structure, consisting of many small subunits, can be found among interplanetary dust grains and in cometary bodies (Brownlee et al. 1980; Greenberg & Hage 1990; Hu & Winarski 2011). Although no direct evidence shows that interstellar dust grains assume the same structure, data analysis from remote observation supports the existence of aggregate structure among interstellar dust grains (Jones 1988; Woo et al. 1994; Wurm et al. 2003). Photopolarimetry also indicates that interstellar and cometary dust consists of micron-sized aggregates which consist of sub-micron-sized subunits

and places limits on the porosity and composition of the grains (Kolokolova & Mackowski 2012; Lasue & Levasseur-Regourd 2006; Kimura et al. 2006). The charging of aggregate dust grains has been studied recently both in laboratory and astrophysical environments (Wiese et al. 2010; Ilgner 2012; Okuzumi et al. 2011); these results have shown that aggregates tend to acquire more charge when compared to spherical grains of the same mass due to the porous/fluffy structure of the aggregate, and that charged aggregates have a significant effect on subsequent dust evolution. However, there has not been a detailed study of characterizing the charge on aggregates based on structural characteristics.

In this paper, a three-dimensional model is employed to calculate the charge on aggregate dust grains under charging conditions particular to solar system environments. Three different charging processes are taken into account—plasma charging currents, secondary electron emission, and UV radiation. For charging processes dominated by secondary electron emission at the heliopause, we show a charge enhancement for all the aggregates compared to spheres of the same mass. This charge-to-mass ratio is significantly higher for aggregates consisting of nano-sized grains as a result of the small particle effect. For photoemission, the charge on aggregates may be more or less than the charge on spheres with the same mass, depending on the magnitude of the variable solar UV photon flux. Charge estimate models are proposed for both secondary electron emission and photoemission, and it is shown that the charge on aggregates can be estimated based on structural characteristics such as the compactness factor.

2. CHARGING MODEL

The charge on a dust grain embedded in plasma is determined by

$$\frac{dQ}{dt} = \sum_j I_j,$$ (1)

where I_j is the current contributed by the jth charging process. The charge on the grain reaches equilibrium when $\sum_j I_j = 0$. For an isolated spherical grain, Equation (1) can be solved analytically to yield the equilibrium charge (Goertz 1989). However, this highly idealized circumstance is almost never satisfied in astrophysical environments. As discussed above, the cosmic dust grains often assume irregular shapes, and thus require numerical simulation. The charging current densities for three charging processes—plasma charging, secondary electron emission, and photoelectric emission—are given below. Silicates have been identified as one of the major constituents for cosmic dust grains (Savage & Mathis 1979; McCarthy 1980), thus silicate grains with a density of 3.2 g cm^{-3} (Draine & Salpeter 1979) are used as the grain material in this study to demonstrate the different charging processes.

2.1. Collection of Plasma Particles

The current density to a spherical grain can be found from Orbital Motion Limited theory (OML), which is based on the conservation of energy and angular momentum (Whipple 1981; Laframboise & Parker 1973). The current density to any point on the surface of a grain due to the collection of a given species of plasma particles is given by

$$J_s = n_s q_s \iiint v_s f(\boldsymbol{v}_s) \cos\alpha \, d\boldsymbol{v}_s^3,$$ (2)

where n_s and q_s are the number density and charge of the given species, v_s is the speed of the particles, $f(\boldsymbol{v}_s)$ is the distribution function which is assumed to be Maxwellian (Goertz 1989), and α is the angle between the impinging velocity and the surface normal of the dust grain. In the three-dimensional case, we use spherical coordinates (v, θ, ϕ) in $\boldsymbol{v}$ space (Laframboise & Parker 1973). The differential velocity $d\boldsymbol{v}_s^3$ can be written as

$$d\boldsymbol{v}_s^3 = v^2 \, dv \, d\Omega.$$ (3)

This allows the integration over the speed to be separated from the integral over the open solid angles, allowing Equation (2) to be rewritten as

$$J_s = n_s q_s \int_{v_{\min}}^{\infty} v_s^3 f(v_s) \, dv_s \iint \cos\alpha \, d\Omega.$$ (4)

The integration over speed is easy to carry out with $v_{\min}$ given by

$$v_{\min} = \begin{cases} 0, & q_s \varphi \geqslant 0 \\ \sqrt{\dfrac{-2q_s\varphi}{m_s}}, & q_s \varphi < 0 \end{cases},$$ (5)

where φ is the surface potential of the grain and m_s is the mass of the plasma particle. For a point on the surface of an isolated sphere, the integral over the open solid angles (a hemisphere) is also simply evaluated. However, on the surface of an aggregate, not all of the incident angles are open to the incoming particle flux. Thus, the differential solid angle $d\Omega$ requires numerical simulation for aggregates, which is discussed in Section 2.4.

2.2. Secondary Electron Emission

Energetic primary electrons can release secondary electrons from the surface of a grain upon impact, which constitutes a positive charging current. It has been shown that the secondary electron yield is enhanced when the dimensions of the monomers are comparable to the primary electron penetration depth, the so-called small particle effect (Chow et al. 1993). Since the size of a representative interstellar dust grain is normally less than 10 μm, we employ a model which takes the small-particle effect into account in determining the yield, δ, as a function of E_0, the initial energy of the primary electron (Draine & Salpeter 1979),

$$\delta(E_0) = \delta_m \frac{8E_0/E_m}{(1 + E_0/E_m)^2} \left[1 - \exp\left(\frac{-4a}{3\lambda}\right) \right] f_1\left(\frac{4a}{3R}\right) f_2\left(\frac{a}{\lambda}\right).$$ (6)

Here

$$f_1(x) = \frac{1.6 + 1.4x^2 + 0.54x^4}{1 + 0.54x^4}$$
$$f_2(x) = \frac{1 + 2x^2 + x^4}{1 + x^4},$$ (7)

and a is the radius of the grain. The maximum yield, δ_m, and the corresponding maximum energy, E_m, are 2.4 and 400 eV for silicates (Mukai 1981). The escape length λ is 2.3 nm (Draine & Salpeter 1979). The projected range R gives the penetration depth of a primary electron into matter along the incident direction and is determined based on E_0 as shown by Draine & Salpeter (1979).

Thus, the current density due to secondary electron emission is calculated as

$$J_s = n_e q_e \iiint v f(v) \cos\alpha \, \delta(E_0) \, d\boldsymbol{v}^3 \times \int_{E_{\min}}^{\infty} \rho(E) \, dE,$$ (8)

where $\rho(E)$ is the energy distribution of the emitted electrons. It can be written as

$$\rho(E) = \frac{E}{2(kT_{\text{sec}})^2}\left[1 + \frac{1}{2}\left(\frac{E}{kT_{\text{sec}}}\right)^2\right]^{-3/2}, \qquad (9)$$

where T_{sec} is the temperature of the emitted electrons and is set to be 2 eV (Goertz 1989). The lower limit of the integral is $E_{\text{min}} = \max(0, e\varphi)$, with φ being the surface potential of the target grain. Equation (3) can be used in Equation (8) to yield

$$J_{\text{sec}} = n_e q_e \int_{v_{\text{min}}}^{\infty} v^3 f(v)\delta(E_0)dv \iint \cos\alpha\, d\Omega \int_{E_{\text{min}}}^{\infty} \rho(E)dE, \qquad (10)$$

which has a form similar to that of Equation (4), with the only term dependent on the geometry of the aggregate being the integral over $d\Omega$.

2.3. Photoelectric Emission

Incoming photons with energy $h\nu > W$, the work function of the material, can excite and liberate electrons from the surface, and thus constitute a positive charging current. Assuming an isotropic source of UV, the photoelectric current density can also be separated into integration over the photon energy and the incident angles (Kimura & Mann 1998a):

$$J_{\text{ph}} = q_e \int_W^{\infty} Q_{\text{abs}}(h\nu)F(h\nu)Y(h\nu)\, d(h\nu)$$
$$\times \iint \cos\alpha\, d\Omega \int_{E_{\text{min}}}^{E_{\text{max}}} f(E)\, dE, \qquad (11)$$

where $h\nu$ is the photon energy and $F(h\nu)$ is the photon flux at a given distance from the Sun, which can be easily obtained through satellite measurements. The absorption efficiency Q_{abs} depends on the grain radius a and the wavelength of the incoming photon, λ. If $2\pi a > \lambda$, the interaction of the grain and the photon can be regarded as elastic scattering and $Q_{\text{abs}} = 1$. If $2\pi a < \lambda$, Mie scattering is often used to obtain Q_{abs} (Bohren & Huffman 1983). The work function of silicates, W, is 8 eV based on empirical value (Draine & Salpeter 1979). The photoelectric yield $Y(h\nu)$ is estimated using (Draine & Salpeter 1979)

$$Y(h\nu) = \frac{(h\nu - W + \epsilon_{\text{min}})^2 - \epsilon_{\text{min}}^2}{(h\nu)^2 - \epsilon_{\text{min}}^2}\left[1 - \left(1 - \frac{l_e}{a}\right)^3\right], \quad (12)$$

where the escape length of the photoelectrons l_e is 1 nm for silicates (Draine & Salpeter 1979). ϵ_{min} is the minimum energy needed for photoelectric emission to occur and is set to 6 eV for silicates (Draine & Salpeter 1979).

The energy distribution of the photoelectrons is given by $f(E)$ and must be taken into account if the potential distribution about the surface is such that some of the photoelectrons return instead of escaping. Both laboratory and space experiments indicate that the photoelectrons are emitted isotropically with a Maxwellian distribution for the energy at a characteristic temperature of 1–2 eV (Hinteregger et al. 1959; Grard 1973; Wrenn & Heikkila 1973). Thus, the energy distribution $f(E)$ of the photoelectrons is

$$f(E) = \frac{E}{(kT_{\text{ph}})^2}\exp\left(-\frac{E}{kT_{\text{ph}}}\right), \qquad (13)$$

with temperature T_{ph} of the photoelectrons set to be 1 eV in the current study. The lower limit E_{min} of the integration is $\max(0, e\varphi_s)$. Thus, the integration yields

$$\int_{E_{\text{min}}}^{\infty} f(E)\, dE = \begin{cases} 1, & q_e\varphi_s < 0 \\ \exp\left(-\frac{q_e\varphi_s}{kT_{\text{ph}}}\right), & q_e\varphi_s \geqslant 0. \end{cases} \qquad (14)$$

With the aid of Equation (14) the photoelectric current density can be written as

$$\begin{cases} J_{\text{ph}} = q_e \int_W^{\infty} Q_{\text{abs}}(h\nu)F(h\nu)Y(h\nu)\, d(h\nu) \\ \qquad \times \iint \cos\alpha\, d\Omega, & q_e\varphi_s < 0 \\ J_{\text{ph}} = q_e \exp\left(-\frac{q_e\varphi_s}{kT_{\text{ph}}}\right)\int_W^{\infty} Q_{\text{abs}}(h\nu) \\ \qquad \times F(h\nu)Y(h\nu)\, d(h\nu) \iint \cos\alpha\, d\Omega & q_e\varphi_s \geqslant 0. \end{cases} \qquad (15)$$

Once again, the current density depends on the aggregate geometry through the integral over the open angles. The above equation assumes an isotropic UV flux, while the solar flux is decidedly anisotropic. Since only the side of an aggregate currently facing the Sun is illuminated, the photon current is estimated by dividing by a factor of two, as the rotational period of a micron-sized dust grain is very short compared to the equilibrium charging time (see Section 3.2). While this correction is exact for a spherical grain, given the irregular surface of an aggregate and the shadowing effect, this gives an upper bound for the photoelectric current for an aggregate.

2.4. Line-of-sight Approximation

The charging code OML_LOS calculates the electron and ion fluxes by determining the open lines of sight (LOS) to the points on the surface of each constituent monomer. A detailed description can be found in Matthews et al. (2012); here a brief summary is given. Electrons and ions coming from the surrounding plasma are assumed to move in straight lines and are captured at the points at which their straight-line trajectory intersects a monomer, as illustrated in Figure 1.

The surface of each monomer is divided into many equal-area patches. Test directions t from the center of each patch (the so-called LOS) are determined to be *blocked* if they intersect any other monomer in the aggregate or the monomer in question ($\text{LOS}_t = 0$), and *open* otherwise ($\text{LOS}_t = 1$). The integration over the angles in Equations (4), (10), and (15) is replaced by the LOS factor, which is equal to the sum of the open LOS multiplied by the cosine of the angle of the test direction with respect to the surface normal and by the area of the patch on a unit sphere, $\text{LOS} = \iint \cos\alpha\, d\Omega = \sum_t \text{LOS}_t \cos\alpha_t \Delta(\cos\theta)\Delta\phi$. The net current of species s to a given patch at a given time, $I_s(t)$, is found by multiplying the current density by the area of the patch, A: $I_s(t) = J_s(t)A$. Summing over species s provides the change in the surface charge on the patch during a time interval dt, $dQ(t) = \sum I_s(t)dt$. The contribution to the dipole moment is given by $d\mathbf{D}(t) = \sum I_s(t)\mathbf{R}dt$, where $\mathbf{R}$ is the displacement vector from the patch to the center of the grain. The current density $J_s(t)$ depends on the potential at the center of the given patch, which in turn depends on the charge and dipole moment on each monomer,

$$V_{\text{patch}} = \frac{1}{4\pi\epsilon_0}\left(\sum_i \frac{Q_i}{r_i} + \sum_i \frac{\mathbf{D}_i \cdot \mathbf{r}_i}{|\mathbf{r}_i|^3}\right), \qquad (16)$$
Figure 1. Open lines of sight to given points on a monomer in an aggregate are indicated by the shaded regions. Charging currents to a given point are only incident from these directions. The dotted line indicates an emitted electron which is recaptured by another monomer along a closed line of sight, while the dash-dotted line indicates an emitted electron that escapes along a free line of sight.

where Q_i and $\mathbf{D}_i$ are the charge and dipole on the ith monomer, and $\mathbf{r}_i$ is the distance vector from the center of the ith monomer to the patch. The solution requires numerical iteration until equilibrium is reached. The change in the charge and dipole moment of each monomer is then obtained by adding the contribution of all the patches. The change in the charge and dipole moment of the aggregate is obtained by adding the contribution from each of the N monomers. This process is iterated in time until the average change in aggregate charge becomes negligible, $dQ_{\mathrm{agg}} < 0.0001 Q_{\mathrm{agg}}$, at which point the net current to the aggregate will be near zero.

Deviation from a straight-line trajectory is caused by the non-symmetric charge distribution on the aggregate surface. Thus, the dipole moment is the leading term that causes these deviations, and the charge–dipole interactions only become important at distances close to the aggregate. Numerical simulations were performed to check the deviation from straight-line trajectories of charged ions and electrons approaching the surface of a charged aggregate. The calculated deviation, Δ, was in all cases much smaller than a monomer radius, $\Delta \ll a$, even for the smallest monomers used in the aggregates. This means that the eventual point of impact on the monomers coincided with the point obtained using the straight line-of-side approximation within the precision given by the surface density of test points used in our simulations.

In computing the current due to secondary electron emission or photoemission, an electron escapes from the aggregate only if the randomly chosen escape direction is along an open LOS. Electrons that are released along a blocked LOS are recaptured by another monomer within the aggregate, leaving the total charge of the aggregate unchanged, but the charge distribution on the surface is altered. Note, however, that charge is treated as a continuous variable in this model, rather than being quantized in units of elementary charges, so that the emitted and recaptured charge is not quantized. Thus, the emitted electron current is "smeared out" over the surface of the aggregate, which may more accurately portray the effects of photoemission since $2\pi a \ll \lambda$ is not strictly valid for all of the monomers comprising interstellar dust aggregates, requiring the wave nature of light to be taken into account.

2.5. Aggregate Builder and Compactness Factor

The numerical code *Aggregate Builder* was used to create aggregates through the coagulation of spheres using a combination of particle–cluster aggregation (PCA) and cluster–cluster aggregation (CCA; Matthews et al. 2007; Matthews & Hyde 2009). During PCA, a target particle is placed at the origin, and a single particle is released at the boundary of the simulation box with its velocity directed toward the center of target particle plus an offset. A successful collision is detected if constituents of the target and projectile actually touch or overlap. The grains are assumed to have relative velocities that are too low for any restructuring to occur and to stick at the point of contact (Wurm & Blum 1998; Blum & Wurm 2000). New aggregate parameters are then calculated, and the resultant aggregate is saved to a library. In the case of CCA, small aggregates from the previously saved library are employed as the target grains, with the incoming grain either a spherical monomer or an aggregate randomly selected from the same library.

While the structure of the aggregates (characterized by the compactness factor described below) depends on the plasma environment in which it grows, the charge on an aggregate within a given environment is in turn a function of the compactness factor (Matthews et al. 2012). Thus, a large number of aggregates were built covering a wide range of compactness factors assuming a neutral environment. The aggregates from the library were then charged through OML_LOS using the parameters representing different astrophysical environments.

The compactness factor, Φ_σ, defined by Paszun and Dominik (Paszun & Dominik 2009) is used to characterize the structure or fluffiness of an aggregate consisting of spherical monomers:

$$\Phi_\sigma = N \left(\frac{a}{R_\sigma} \right)^3, \tag{17}$$

where N is the number of monomers in the aggregate, a is the constituent monomer radius, and R_σ is the radius of the average projected surface area, defined as

$$R_\sigma = \sqrt{\frac{\sigma}{\pi}}, \tag{18}$$

with σ being the projected surface area averaged over many orientations. Figure 2 shows a representative aggregate consisting of mono-disperse monomers, with R_σ and the outer radius R_{max} indicated. For compact aggregates, the volumes of the two spheres with these radii are approximately equal. For open aggregates, the ratio of the two approaches zero.

Figure 3 shows the log–log plot for the mass of aggregates consisting of mono-disperse monomers of different radii ($5\,\mathrm{nm} \leqslant a \leqslant 500\,\mathrm{nm}$), ranging in size from 2 to 200 monomers, as a function of the compactness factor. For each of the groups, as the mass increases, the compactness factor decreases, indicating a fluffier structure. This power-law relationship confirms that the compactness factor can be used to characterize the structure of the aggregates.

3. RESULTS

3.1. Charging of Aggregates with Secondary Electron Emission

In this section, the charging of aggregates is examined by including both plasma currents and secondary electron emission. The aggregates are charged using parameters for conditions in the heliosheath, the region between the termination shock and
Figure 2. Illustration of the compactness factor. The inner shaded area corresponds to a sphere with radius R_σ, the outer shaded area to a sphere with maximum radius, R_{max}.

(A color version of this figure is available in the online journal.)

the heliopause. The plasma temperature in this region rises to 2×10^6 K, a result of the constant interaction between the solar wind and the interstellar medium. Thus, secondary electron emission is the dominant charging process due to the high electron temperature (Kimura & Mann 1998a). The plasma density and temperature at 150 AU are $n_e = n_i = 2 \times 10^5$ m^{-3} and $T_e = T_i = 2 \times 10^6$ K (Schwenn 1990; Pauls & Zank 1996). It is shown that the collective charge on an aggregate consisting of nano-sized grains is appreciably enhanced due to the small particle effect on each subunit. Two models for approximating charge on aggregates are proposed and the charge-to-mass ratio of the aggregates is compared to that of the spheres with the same mass.

3.1.1. Charging Time

Before estimating the equilibrium surface charge on the aggregates, the time to reach the equilibrium condition needs to be considered, for depending on the plasma parameters and the dynamic processes being considered, the equilibrium condition is not always satisfied for grains of all sizes.

The dominant current determines the polarity of the equilibrium charge, while the non-dominant current determines the charging time, τ_{eq}. As the grain charges, the relative contribution of the non-dominant current increases to balance the

dominant current. Due to the high temperature of the plasma near the heliopause, secondary electron emission is the dominant charging process, determining Q. Thus τ_{eq} can be approximated by $|Q/I_e|$. Generally, τ_{eq} increases with decreasing dust radii a, approximately according to $\tau_{eq} \propto a^{-1}$. Figure 4 shows the charging history of a dimer consisting of two 5 nm radius monomers, the smallest aggregate in the simulation. The maximum charging time is approximately 1×10^6 s, which is less than 5.75×10^6 s, the time needed for interstellar dust grains to travel 1 AU with a constant speed of 26 km s^{-1}. Since the typical distance between the heliopause and termination shock is 50 AU (Schwenn 1990), all the aggregates in the simulation are assumed to reach equilibrium within traveling a distance of 1 AU.

3.1.2. Model for Estimating Aggregate Charge

The equilibrium surface charge on aggregates is plotted using both the number of monomers (Figure 5) and the compactness factor (Figure 6(a)). The aggregates in each group consist of up to 200 mono-disperse monomers with radii ranging from 5 nm to 500 nm. Figure 5 shows that the aggregate charge is related to the number of monomers by

$$Q_{agg} \propto N^{0.413}, \tag{19}$$

where N is the number of monomers within an aggregate.

The aggregate charge can be predicted based on both the number of the monomers or the compactness factor. However, it is difficult, if not impossible, to determine the number of monomers within an aggregate measured in situ, while the compactness factor can be obtained through remote observation. In fact, much research has been devoted to relating the morphological structure of aggregates to their optical properties (Kimura & Mann 1998b; Kimura 2001; Shen et al. 2008). As such, relating the charge to the compactness factor may serve as a useful tool when investigating the dynamics of interstellar dust grains in the outer heliosphere.

The equilibrium charge as a function of the compactness factor is shown in Figure 6(a) for aggregates consisting of mono-disperse spheres with different radii. Each group can be fit with a straight line of the same slope on a log–log plot with charge related to the number of constituent monomers by

$$Q_{agg} \propto \Phi_\sigma^{-1.3}. \tag{20}$$

Figure 3. Mass of aggregates as a function of the compactness factor. The radius of the constituent monomers is given in the legend.
Figure 4. Charging curve for a dimer consisting of two 5 nm radius monomers. τ_{eq} is determined by the point where the absolute change in the charge is less than 0.1% of the equilibrium charge.

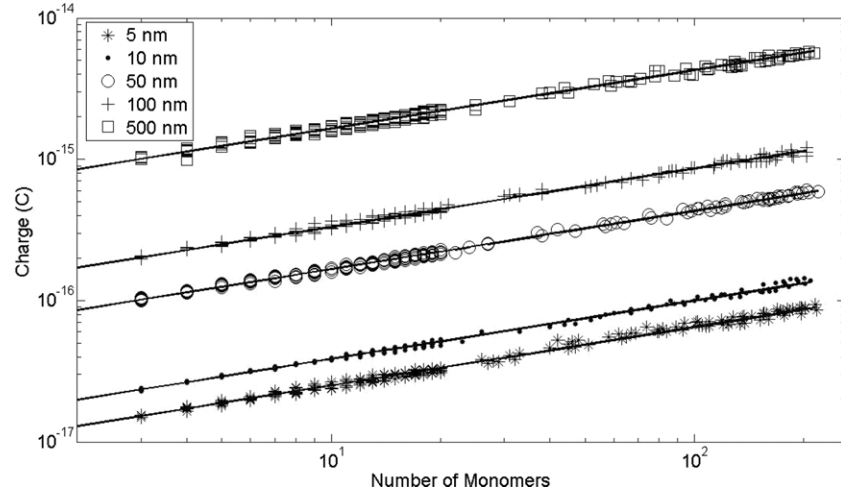

Figure 5. Surface charge on aggregates as a function of the number of constituent monomers. The linear fits have the same slope for all monomer sizes with standard error less than 2%. The radius of the constituent monomers is indicated in the legend.

Figure 6. (a) The charge on aggregates consisting of mono-disperse monomers of different radii, as indicated by the legend, and (b) the surface charge divided by the capacitance of a single monomer. The small particle effect is clearly evident for aggregates composed of monomers of size $a = 5$ nm.
Figure 7. Comparison of the surface potential on aggregates (data points) and spheres having the same mass (solid line). The monomer radius within the aggregates is indicated by the legend.

The results clearly demonstrate that for each group, the surface charge on the aggregate increases as the fluffiness of the aggregate structure increases, with the surface charge of a sphere being the lower limit as Φ_σ approaches one. This indicates that using the surface potential of a sphere of an equivalent mass to calculate the charge on an aggregate leads to charge underestimation.

In Figure 6(b), the charges on the aggregates are divided by $4\pi\epsilon_0 a$, the capacitance of a single monomer, to yield the effective potential for the aggregates. After eliminating the monomer size factor, it can be seen that aggregates consisting of monomers with $a > 10$ nm fall on the same line, while the aggregates with the smallest monomers, $a = 5$ nm, exhibit a substantially higher y-intercept. The aggregates consisting of monomers with $a = 10$ nm lie in between. It is evident that the collective contribution of the higher potential achieved by nm-radius grains (within the much larger aggregate) caused by the small particle effect is significant and needs to be taken into account when estimating the charge on aggregate structures.

In a given plasma environment, spherical grains with $a > 10$ nm reach the same equilibrium potential, independent of their radii, while spheres with radii $a \leqslant 10$ nm have a greater potential due to the small particle effect from secondary electron emissions (Chow et al. 1993). However, as shown in Figure 7, the surface potential of an aggregate clearly does not follow this trend. The surface potential of an aggregate in this case is defined as

$$\varphi = \frac{Q_{\mathrm{agg}}}{4\pi\epsilon_0 r_{\mathrm{mass}}}, \qquad (21)$$

where Q_{agg} is the total charge on the aggregate and r_{mass} is the radius of a solid silicate sphere having the same mass as the aggregate. Overall, the surface potential of aggregates shows larger differences for a given mass and is generally greater than that of a sphere with the same mass, due to the greater surface area of the aggregate. Aggregates consisting of monomers with $a = 5$ nm and 10 nm have a surface potential which is significantly higher (up to 2–3 times greater for an aggregate consisting of 200 monomers) than that for a sphere with the same mass. This is caused by the high positive charge each constituent monomer carries as a result of the small particle effect, consistent with prediction (Kimura & Mann 1998a). A similar effect has been seen in an experimental study, where the

charge on aggregates differed from those on spheres by up to an order of magnitude (Wiese et al. 2010). The greater difference observed in this experiment is likely due to the anisotropy of the plasma parameters in the sheath, which can result in much more negative charge on dust grains, depending on their position in the sheath (Douglass et al. 2011). Since the calculation in Wiese et al. does not completely include this anisotropy, part of the much higher negative charge (an order of magnitude, rather than a factor of two) can be explained by the fact that the dust grain is levitated in the sheath. Furthermore, in the experiment, the position of the grain in the sheath is determined by using small grains as markers for the sheath edge. This method is not conclusive (Douglass et al. 2012), which makes the plasma parameters at the position of the grain in the experiment uncertain. Nonetheless, even given these considerations, the observed charge is much higher than expected and points to the effect of the porosity of the grains on the enhanced charging, similar to the results presented here.

3.2. Charging of Aggregates with UV Radiation

The typical plasma environment at 1 AU is used to illustrate charging by photoemission, as photoemission is the dominant charging process at this distance (Kimura & Mann 1998a). Plasma and UV radiation parameters vary greatly over spatial distance and with time. However, the current purpose is to demonstrate the charging of aggregate grains compared to spherical grains, so more emphasis is placed on the characteristics of aggregate charging rather than modeling a specific environment. The plasma density and temperature at 1 AU are $n_e = n_i = 6 \times 10^6$ m^{-3} and $T_e = T_i = 2 \times 10^5$ K (Schwenn 1990). Only electrons and singly ionized hydrogen are considered, with other plasma components neglected due to their relatively small contribution (Schwenn 1990). Instead of simulating the photon flux in specific regions and time periods, the product of the absorption efficiency, yield and solar flux integrated over the spectrum (the first integral in Equation (15)) is left as a free parameter and varied from 5×10^{12} m^{-2} s^{-1} to 1.5×10^{13} m^{-2} s^{-1}, within the photoemission current densities expected at 1 AU (Whipple 1981; Tobiska 1991). The constituent monomers are taken to be silicate grains with radii $a = 50$ nm and 1 μm. With a work function of 8 eV for silicates, the long wavelength cutoff is 1550 Å. The absorption
Figure 8. Evolution of charge on aggregates compared to that of an equivalent sphere. The photoemission current density is 1.2×10^{13} m^{-2} s^{-1} in (a), 9×10^{12} m^{-2} s^{-1} in (b), and 6×10^{12} m^{-2} s^{-1} in (c). The aggregate charge shown is the average for six different aggregates with $N = 13$ monomers.

efficiency $Q_{abs} \approx 1$, as $2\pi a$ exceeds the photon wavelength, and detailed calculations using Mie theory for the smallest grains did not significantly change the results. The small particle effect for photoemission is also neglected due to the large radius of the grains.

In Figure 8, the time evolution of the aggregate surface charge is compared to that of an equivalent sphere for three

different photoemission current densities of 6×10^{12} m^{-2} s^{-1}, 9×10^{12} m^{-2} s^{-1}, and 1.2×10^{13} m^{-2} s^{-1}, respectively. The results indicate that aggregates and spheres may have charges of opposite polarity under the same conditions (Figure 8(c)), and may be either more or less highly charged than an equivalent sphere depending on the magnitude of the photoemission current density compared to the plasma current density (Figures 8(a) and (b)). This is due to the porous structure of the aggregate. A highly irregular object has a greater surface area and is thus able to absorb more of the emitted electrons, as also shown in a recent experimental study (Wiese et al. 2010). By the same token, when the photoemission current is very strong, the porous aggregate has more surface exposed to the UV photons, yielding a greater positive charge.

3.2.1. Model for Estimating Aggregate Charge

Again, we characterize the equilibrium charge on the aggregates due to plasma and photoelectric charging using both the number of monomers and the compactness factor. Using a photoemission current density of 1.1×10^{13} m^{-2} s^{-1}, the charge on aggregates is plotted as a function of the number of monomers and the compactness factor in Figure 9. Based on Figure 9(a), the charge can be estimated as a function of the number of monomers,

$$Q_{agg} \propto N^{0.42}, \qquad (22)$$

where N is the number of the monomers within an aggregate. Figure 9(b) indicates that a linear relationship on a log–log scale can also be obtained for the charge and the compactness factor,

$$Q_{agg} \propto \Phi_{\sigma}^{-1.3}. \qquad (23)$$

The same exponential factor for both monomer sizes serves as strong evidence that aggregate charge is a function of the

aggregate structure. The charge on aggregates can be estimated either by the number of the constituents or the structural characteristics (fluffiness of the aggregate). While determining the charge on an aggregate based on the number of constituent monomers seems intuitive, the information is often hard or infeasible to obtain. Structural characteristics, on the other hand, can be obtained through the scattering and absorption interaction between aggregates and light. The power-law relation between the compactness factor and the aggregate charge also provides an indirect but a rather accurate method of determining the morphology of interplanetary dust. The Cosmic Dust Analyzer on the *Cassini* spacecraft has successfully detected the charge on interplanetary dust (Kempf et al. 2004). If the composition and size distribution of these grains is known, along with the solar wind conditions, the structure of these grains may be obtained based on the charge estimate models proposed above.

4. DISCUSSION AND CONCLUSION

A numerical model has been used to calculate the charge on aggregate structures in astrophysical environments, including primary plasma currents, secondary electron emission, and photoemission. It is shown that the charge on aggregates is strongly correlated to structural characteristics (Figures 6 and 9(b), as measured by the compactness factor). In general, porous aggregates, with their greater surface area, are more highly charged than an equivalent mass sphere, with the sign of the charge being determined by the dominant charging current. The substantial increase in charge-to-mass ratio for aggregates in the region of the heliosphere (Figure 7) will have a significant effect on the dynamics of these grains, greatly influencing the mass distribution of interstellar dust grains detected within the solar system by instruments such as the dust detector on *Ulysses*.

It is interesting to note that the relationship between charge and structural factors (Equations (19), (20), (22), (23)) is the same for the two different charging environments. This is a result of the LOS factor for an aggregate being independent of the monomer size within the aggregate, as long as all of the spherical monomers have the same radius. The relationship between charge and aggregate structural characteristics for polydisperse monomer populations is the subject of current research.

Finally, the relationship between the charge on an aggregate and the charge on an equivalent sphere can vary greatly depending on the magnitude of the non-plasma currents. This is seen for the aggregates charged by photoemission in Figure 8. The values used for the photoemission current density in the three cases shown are all within the range expected for solar UV flux at 1AU, which varies greatly depending on solar activity. Thus, the charging history of aggregates in space can vary greatly over time and is markedly different from the charging history of a spherical grain. Further results exploring these differences will be presented in an upcoming paper.
